Ankylosing spondylitis (AS) is frequently associated with inflammatory lesions of the spine and continuous fatigue stress fractures; however, an association with an intraspinal synovial cyst has not been previously reported. A 55-year-old man with a five year history of AS who presented with back pain and a right radiculopathy was admitted to the hospital. Five years previously, he underwent a percutaneous vertebroplasty for an osteoporotic L1 compression fracture, and was diagnosed with AS at that time. Plain radiographs showed aggravated kyphosis and a stress fracture through the ossified posterior element, below the prior vertebroplasty. Magnetic resonance images revealed a right foraminal cystic lesion at the L2-L3 level with effacement of the nerve root. A 1.6 cm cystic lesion that appeared to arise from the L2-L3 facet joint without direct communication was excised from the L2-L3 foramen. Pathological examination confirmed synovial cyst. The patient’s symptoms resolved immediately after surgery except for a mild dysesthesia of the right leg. We report herein a rare case of foraminal synovial cyst associated with AS accompanying posterior element fracture with a review of literature.

Key Words : Synovial cyst ∙ Ankylosing spondylitis.

INTRODUCTION

Synovial cysts usually develop from the synovial capsule of the facet joints. Although their etiology is unclear, facet joint arthropathy and underlying spinal instability are known to be associated with the formation of synovial cysts and worsening symptoms1,2,3. Most intraspinal synovial cysts are located in the lower lumbar spine, where the greatest degree of movement is present4. In rare cases, they have also been described with inflammatory changes of the facet joints in association with rheumatoid arthritis and undifferentiated spondyloarthropathy2,5,6. However, there has been no report of intraspinal synovial cysts associated with ankylosing spondylitis (AS). We report a patient who developed a radiculopathy caused by foraminal synovial cyst associated with AS accompanying posterior element fracture.

CASE REPORT

A 55-year-old man with a five year history of AS was admitted to our institute with severe back pain and right thigh pain. Five years previously, he developed severe back pain after a light fall and the magnetic resonance imaging (MRI) revealed a fresh compression fracture at L1. The patient was diagnosed with AS at that time. Plain radiographs showed aggravated kyphosis and a stress fracture through the ossified posterior element, below the prior vertebroplasty. Magnetic resonance imaging revealed a right foraminal cystic lesion at the L2-L3 level with effacement of the nerve root. A 1.6 cm cystic lesion that appeared to arise from the L2-L3 facet joint without direct communication was excised from the L2-L3 foramen. Pathological examination confirmed synovial cyst. The patient's symptoms resolved immediately after surgery except for a mild dysesthesia of the right leg. We report herein a rare case of foraminal synovial cyst associated with AS accompanying posterior element fracture with a review of literature.

sion was identified in the neural foramen and dorsal to right L2 nerve root. The cyst was filled with a dark yellowish fluid and it was totally resected. On pathological examination, a fibroconnective tissue and synovial membrane was observed (Fig. 5). The patient’s postoperative course was uneventful. The symptoms resolved immediately after surgery except for a mild dysthesia and he remained free of thigh pain 15 months after surgery.

DISCUSSION

Several theories have been suggested on the origin of synovial cysts. Most are contiguous with the facet joint capsule itself. Other theories suggest displaced cell rests of synovium, degeneration of the collagenous tissue of the joint capsule, or neoformation from articular tissue resulting from chronic irritation and inflammation. Symptomatic synovial cysts of the facet joints in the lumbar spine have been the focus of study recently. The most common cause reported is degenerative facet joint disease with hypertrophy and herniation of synovium through a tear of the capsule. Rarely, cysts have been observed to develop secondary to rheumatoid arthritis. However, there have been no cases reported in association with AS; although Vergne et al. considered the possibility of this association. As the synovial fluid not only exists in the spinal canal, but also appears in ligament or tendons, there is possibility for it to be occurred without attaching with facet joint. We, however, could not find any case which developed foraminal location at L2-L3 level. In this case, as the actual section of the facet joint was undefinable due to ankylosis of AS, we could not conclude whether the connection with facet joint exists or not, but considering the levels and location, in the case of synovial cyst that was not detected in the initial MRI taken 5 years ago, the possibility of formation of intraspinal synovial caused by chronic irritation by posterior segment fracture as the natural course of AS is worth taking into consideration. Although a casual relationship cannot be definitely established, spondylolisthesis was absent and there was no history of trauma. The occurrence of this finding in a patient with AS might be explained predominantly by an enthesitis rather than arthritis, which might make it less likely to cause a synovitis initially. A synovial cyst that develops from arthritis in a facet joint later in the course of the disease might not protrude through the ossified periarticular ligaments. Osteoporosis is a well-known complication of AS, and bone loss is the result of changes in the material and structural properties of bone; these changes lead to an increased risk of stress fractures. During the early course of AS, a simple osteoporotic compression fracture occurred after a minor inju-
ry in the patient reported here. Over time, with the chronic spinal inflammation the vertebrae likely fused together at the posterior segment fracture through the facet joints and appeared as chronic findings identified as sclerosis at the fracture margins along with pseudoarthrosis. This case showed sagittal imbalance as a consequence of the old compression fracture in the first lumbar vertebral body. Kyphosis secondary to a compression fracture indicates greater axial distraction stress or force loaded onto the posterior segment and the facet joint adjacent to the fracture level compared to normal spinal alignment. Finally, it is possible that the long-standing effects of repetitive stress caused by sagittal imbalance and the natural course of the increased vertebral stiffness were concentrated at the adjacent posterior element, through the facet joints and might have been contributing factors causing the stress fracture of the posterior element and the synovial cyst.

**CONCLUSION**

The findings of this case suggest that intraspinal synovial cysts may be associated with AS. It is important to aware of the natural course of AS and the possibility that continuous axial distraction stress can cause a posterior segment fracture and adjacent intraspinal synovial cyst.
